The evolution of eusociality is one of the major transitions in evolution, but the underlying genomic changes are unknown. We compared the genomes of ten bee species that vary in social complexity, representing multiple independent transitions in social evolution, and report three major findings. First, many important genes show evidence of neutral evolution as a consequence of relaxed selection with increasing social complexity. Second, there is no single road map to eusociality; independent evolutionary transitions in sociality have independent underpinnings. Third, though clearly independent in detail, these transitions do have similar general features, including an increase in constrained protein evolution accompanied by increases in the potential for gene regulation and decreases in diversity and abundance of transposable elements. Eusociality may arise through mechanisms each time, but would likely always involve an increase in the complexity of gene networks.

The evolution of eusociality involves changes in the unit of natural selection, from the individual to a group (1). Bees evolved eusociality multiple times and are extremely socially diverse (2) (Fig. 1), but all pollinate angiosperms, including many crops essential to the human diet (3). Simple eusociality may be facultative or obligate, and both forms are characterized by small colonies with a reproductive queen and one or more workers that, due to social and nutritional cues, forego reproduction to cooperatively care for their siblings (2). Further evolutionary elaborations have led to complex eusociality, "superorganisms" with colonies of several thousand individuals, sophisticated modes of communication, and morphological specializations for division of labor (4).

Theory predicts that the evolution of simple eusociality involves increased regulatory flexibility of ancestral gene networks to create specialized reproductive and non-reproductive individuals, and the evolution of complex eusociality requires genetic novelty to coordinate emergent properties of group dynamics (5). To test these predictions, we analyzed five de novo and five publicly available draft genome sequences of ten bee species from three families, representing two independent origins of eusociality in Apidae and Halictidae and two independent elaborations of simple to complex eusociality in two apid tribes [Apini (honey bees) and Meliponini (stingless bees); Fig. 1]. The draft genomes were of comparable, high quality (supplementary online text).

We found that the transition from solitary to group life is associated with an increased capacity for gene regulation. We scanned the promoter regions of 5,865 single-copy orthologs among the ten species to calculate a motif score (representing the number and binding strength of experimentally characterized transcription factor binding sites [TFBSs]) for 188 *Drosophila melanogaster* TFs (6) with at least one ortholog in each of the ten bees, and correlated motif score with social complexity, using phylogenetically independent contrasts (7). Of 2,101 significantly correlated motif-gene pairs, 89% were positive and 11% negative, show-

ing that TFs tend to have increased capacity to regulate genes in eusocial species of bees, relative to solitary species (Fig. 2A, supplementary online text).

Further evidence for increased capacity for gene regulation throughout social evolution is a positive ranked correlation between social complexity and the number of genes predicted to be methylated (7) (Spearman's rho = 0.76, p = 0.01; phylogenetically corrected Spearman's rho = 0.64, p = 0.06; Fig. 2B; bioinformatics

predictions validated with bisulfite sequencing data for three invertebrate species; supplementary online text). DNA methylation affects gene expression in a variety of ways (8). Thus, this result suggests an expansion in regulatory capacity with increasingly sophisticated sociality.

The potential for increased regulatory capacity was further revealed at the protein coding level. Increased social complexity also is associated with rapid evolution of genes involved in coordinating gene regulation. A Bayesian phylogenetic covariance analysis (9) of 5,865 single-copy orthologs identified 162 genes with accelerated evolution in species with increased social complexity (7) (Additional Data table S3). These rapidly evolving genes were significantly enriched (p < 0.05) for Gene Ontology terms related to regulation of transcription, RNA splicing, ribosomal structure, and regulation of translation (supplementary online text and tables S11 and S12). Similar results have been reported for bee and ant species (10-13); our findings reveal the underlying causes. Approximately two-thirds of these genes are under stronger directional selection in species with increasingly complex eusociality, but we also detected non-adaptive evolution. One-third of the rapidly evolving genes are under relaxed purifying selection in species with complex eusociality, possibly due to reduced effective population sizes (14).

We also found an additional 109 genes, significantly enriched (p < 0.05) for functions related to protein transport and neurogenesis, which evolve slower with increased social complexity (supplementary online text, table S13, and Additional Data table S3). This includes orthologs of *derailed 2* and *frizzled*, which function as Wnt signaling receptors in *Drosophila* synaptogenesis (15), and *rigor mortis*, a nuclear receptor involved in hormone signaling (16). A similar pattern of reduced evolutionary rate has been described for genes expressed in human and honey bee brains, potentially due to increasing pleiotropic constraint in complex gene networks (17, 18). Constrained protein evolution of neural and endocrine related genes seems at odds with the evolution of complexity, but this constraint appears to be com-

pensated for, or perhaps driven by, increased capacity for gene regulation.

We next investigated whether these molecular evolution patterns involve similar sets of genes and cis-regulatory elements among the early (facultative and obligate simple eusociality) and advanced (complex eusociality) stages of independent social transitions. We identified lineagespecific differences in coding sequences and promoter regions of 1,526 "social genes" for which evolutionary rate (dN/dS) is faster or slower with increased social complexity in two independent origins and two independent elaborations of eusociality (7) (Fig. 1). Among these lineage-specific social genes, we found common patterns of *cis*-regulatory evolution: gains of TFBSs in the promoters of genes that evolve slower with increasing social complexity (Fig. 2C and supplementary online text). This suggests that a shared feature of both independent origins and elaborations of eusociality is increasingly constrained protein evolution with increasing potential for novel gene expression patterns. The TFs responsible for this pattern were different for each social transition, even though our analysis was limited to highly conserved TFs (Table 1). Several function in neurogenesis, neural plasticity, or are prominent regulators of endocrine-mediated brain gene expression in honey bees (19, 20).

We found further lineage-specific differences among the rapidly evolving "social genes" themselves. Genes undergoing accelerated evolution at the origins of eusociality were significantly enriched for GO terms related to signal transduction in both Apidae and Halictidae, but they shared only six genes (6 out of 354 and 167 genes, respectively; hypergeometric test, p = 0.82; Fig. 2D; Additional Data tables S5 and S6). Rapid evolution of signal transduction pathways may be a necessary step in all origins of eusociality to mediate intracellular responses to novel social and environmental stimuli (10), but selection appears to have targeted different parts of these pathways in each independent transition. Caste-specific expression and other analyses of these genes are needed to determine their function in eusociality.

Genes showing signatures of rapid evolution with the elaborations of complex eusociality were also highly disparate between honey bees and stingless bees, with only 43 shared genes and no shared enriched GO terms (43 out of 625 and 512 genes, respectively; hypergeometric test, p = 0.70; Fig. 2D; Additional Data tables S5 and S6). In addition, only 2 out of 5,865 single-copy orthologs showed a signature of convergent evolution by fitting a dendrogram based on social complexity significantly better than the accepted molecular phylogeny (7) (supplementary online text and fig. S21). Similarly, families of major royal jelly protein genes, sex determining genes, odorant receptors, and genes involved in lipid metabolism expanded in some, but not all, lineages of complex eusocial bees (7) (Table 2; supplementary online text). These results suggest gene family expansion is associated with complex eusociality as predicted (5), but involves different genes in each case. Despite striking convergence of social traits among the superorganisms (4), the final stages of transformation to this level of biological organization do not necessarily involve common molecular pathways.

The major transitions in evolution involve a reduction in conflict as the level of natural selection rises from the individual to the group (I). Extending this to intragenomic conflict may explain our finding of decreased diversity and abundance of transposable elements (TEs) with increasing social complexity (T) (regression after phylogenetic correction, T = 8.99, adjusted T = 0.47, T = 0.017; T = 2E and figs. S42-S44; supplementary online text). This may be a consequence of increased recombination rates among highly eusocial insects (T = 2T ) or because key features of complex eusociality lead to decreased exposure to parasites and pathogens that horizontally transmit TEs (T, 2T). Eusociality in bees may thus provide natural immunity against certain types of intragenomic conflict.

Our results and those in refs. 10-13 support the prediction that changes in gene regulation are key features of evolutionary transitions in biological organization (5). Our results further reveal the convergent adaptive and nonadaptive evolutionary processes common to both the early and advanced stages of multiple independent transitions from solitary to group living. It is now clear that there are lineage-specific genetic changes associated with independent origins of eusociality in bees, and independent elaborations of eusociality in both bees and ants. This includes different sets of genes showing caste-biased expression across species (24–26) and, as we have shown, evolutionary modifications of TEs, gene methylation, and cis-regulatory patterns associated with the suite of life history traits that define eusociality. This suggests that if it were possible to "replay life's tape" (27), eusociality may arise through different mechanisms each time, but would likely always involve an increase in the complexity of gene networks.

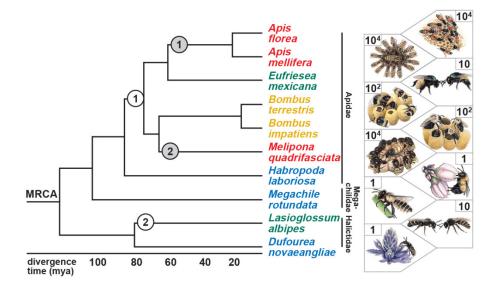

Fig. 1. Phylogeny and divergence times (28) of bees selected for genome analysis. We analyzed two independent origins of simple eusociality from a solitary ancestor, one each in Apidae (white circle 1) and Halictidae (white circle 2), and two independent elaborations complex eusociality in honey bees (grey circle 1) and stingless bees (grey circle 2). Most bees mate once, but honey bees mate with multiple males. All bees eat pollen and nectar from flowering plants. Species names are colored according to degree of social complexity: blue: ancestrally solitary; green: facultative simple eusociality; orange: obligate simple eusociality; red: obligate complex eusociality. The social biology of E. mexicana is unknown, but is representative of the facultative simple eusocial life history (29). Numbers in each box are approximate colony size on a log scale.

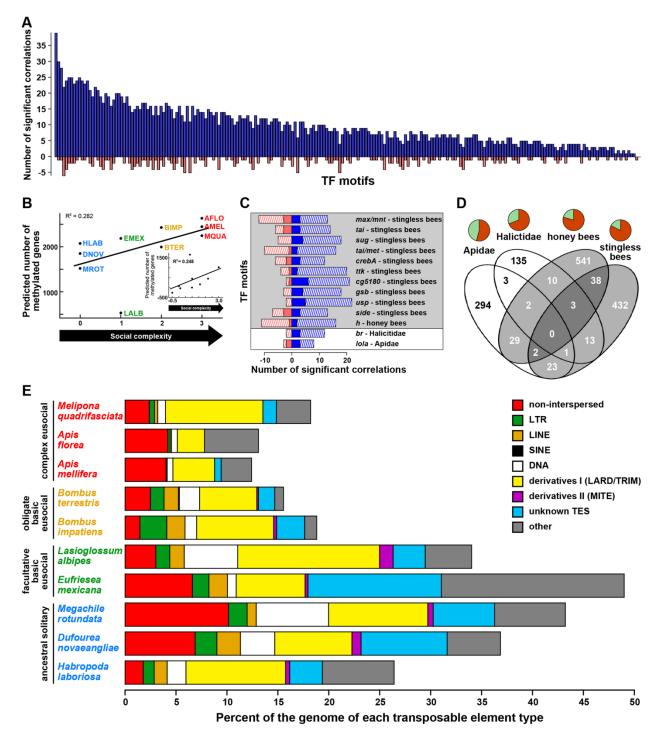

Fig. 2. Genomic signatures of evolutionary transitions from solitary to group life. (A) Increasing social complexity is associated with increasing presence of *cis*-regulatory TFBS in promoter regions. Each bar represents a TFBS for which presence correlates significantly with social complexity (blue: positive; red: negative). (B) Relationship between predicted number of methylated genes and social complexity before and after (inset) phylogenetic correction (see text for statistics). (C) TFBS motifs showing a relationship between social complexity and evolutionary rate of coding and non-coding sequences in different lineages. Bar length indicates the number of significant correlations (blue: positive; red: negative) between each motif score and social complexity (from Table 1) among genes evolving faster (solid) or slower (hatched) in lineages with different levels of social complexity (from 2D). Background shading follows circle shading in Fig. 1. (D) Number of genes for which evolutionary rate is faster or slower in lineages with higher compared to lower social complexity. Pie charts represent the proportion of genes evolving slower (light green) or faster (dark orange) with increased social complexity. Venn diagram shading follows circle shading in Fig. 1. (E) Complex eusocial species have a reduced proportion of repetitive DNA compared to other bees (see text for statistics).

Table 1. Transcription factors (TFs) and corresponding motifs associated with origins and elaborations of eusociality in bees. (Motif names: Fly Factor Survey (6); supplementary online text).
